XIAOYAN DENG and BARBARA E. KAHN*

The authors show that location of the product image on a package facade influences consumers' perceptions of the visual heaviness of the product and evaluations of the package. The "heavier" ("lighter") locations are on the bottom (top), right (left), and bottom-right (top-left) of the package. For products for which heaviness is considered a positive attribute, packages with the product image placed at heavy locations are preferred, whereas for products for which heaviness is considered a negative attribute, packages using light locations are preferred. Furthermore, in the former category (e.g., snacks), a salient health goal, as opposed to a neutral goal, weakens the preference for packages using heavy locations, though this moderating effect of goal is weaker for healthful snacks than for regular snacks. Store shelf context is a boundary condition, such that the location effects on perceived product heaviness and package evaluation appear in a contrasting context but disappear in an assimilating context. Moreover, perceived product heaviness mediates (1) the location effect on package evaluation and (2) the moderating role of store shelf context (i.e., mediated moderation).

Keywords: visual packaging design, product image location, visual perceived heaviness, package evaluation

Is Your Product on the Right Side? The "Location Effect" on Perceived Product Heaviness and Package Evaluation

Packaging is integral to the marketing and distribution of products. At the point of sale, the product package can play a pivotal role in a consumer's purchase decision. Even after the purchase, the packaging can continue to influence the consumption experience. Thus, understanding how packaging variables, such as shape, color, and graphics, affect consumer perception, evaluation, and behavior is of theoretical and managerial importance. Recently, marketing researchers have focused on the effects of package shape on volume perception, package preference, choice, and consumption (e.g., Folkes and Matta 2004; Krishna 2006; Raghubir and Greenleaf 2006; Raghubir and Krishna 1999; Wansink and Van Ittersum 2003; Yang and Raghubir 2005).

In this research, we focus on the relative location of product images on different package facades. Drawing on the art and visual perception literature, we hypothesize and demonstrate a "location effect," in which product images placed at certain locations on a package facade appear to be heavier than the same images placed at other locations. Specifically, we first show that the "heavier" locations are on the bottom, right, and bottom-right of the package facade and that the "lighter" locations are on the top, left, and top-left. We then show that different locations of the product image can influence the shopper's perception of the visual heaviness of the product and that these differing perceptions can affect package evaluation. We further hypothesize and demonstrate that product attribute valence, consumer goal, and store shelf context can moderate this effect. Before we discuss the theoretical justification for our hypotheses, however, we report the findings of a field study in which we observed some systematic patterns regarding how managers are cur-

rently using the location of the product image on a package facade in the actual market place.

FIELD STUDY: THE LOCATION EFFECT OBSERVED IN THE SNACK CATEGORY

We conducted a field study in a metropolitan supermarket in the snack category. We wanted to observe (1) how frequently packaging in this category featured an image of the product; (2) if there was an image, whether the location of the image varied; and (3) whether the pattern of this variation differed in any systematic way.

We investigated two types of snacks: cookies and crackers. We report summary statistics in Table 1, Panel A, which shows that 100% of the snack packages displayed a product image (photography or illustration) on the facade (for examples, see the Web Appendix at http://www.marketingpower.com/jmrdec09). In addition, 61% of the cracker packages featured a health claim (e.g., no trans fat, no or low saturated fat, fat free, no hydrogenated oils, sugar free, no or low cholesterol), whereas only 28% of the cookie packages did ($t(277) = 6.0$, $p < .0001$), suggesting that the cracker category is being marketed as a more healthful category. Consistent with this categorization, 41% of the cracker packages placed the product image at light locations, whereas for cookies (the less healthful option), only 30% of the packages did ($t(277) = 2.0$, $p < .05$). We further examined the relationship between the presence of a health claim on the package and the presence of a product image placed at light locations separately for each category. We report the results in Table 1, Panel B, which shows that for cookies, this relationship was significant ($\chi^2(1) = 31.0$, $p < .0001$), and the presence of a product image placed at light locations was 66% for packages with a health claim and only 17% for those without such a claim ($t(136) = 6.3$, $p < .0001$). For crackers, this relationship showed the opposite pattern, though it was not significant: 38% of the packages with a health claim placed the product image at light locations, whereas 47% of those without a health claim did.

The field study suggests that there are some systematic patterns in the location of the product image on package facades. It appears that the location of the product image is related to product categories and consumers' shopping goals. This is intriguing because our conversations with brand managers and packages designers suggested that the location effect was *not* an effect of which they were conscious. In addition, we found no discussion of this effect in our literature search in packaging trade journals and related articles. However, we know that pictures are more easily recognized and recalled than text (Childers and Houston 1984) and, furthermore, that pictorial information has a profound impact on consumer perception and judgment (Holbrook and Moore 1981). Thus, we are not surprised to observe in our field study that product image was so prevalently used in package design. Given the attention drawn to images, it would also make sense that, at least at an intuitive level, managers might be using product images and their locations to provide product information. Our experiments are designed to provide a roadmap that will help managers predict how the location of the product image on a package facade can be used in a deliberate way to communicate perceptions about the product.

In Study 1, we demonstrate that pictorial objects placed at heavy locations of a visual field appear to be heavier than the same objects placed at light locations. Treating a package facade as the visual field and the product image as a pictorial object within that field, in Studies 2–4, we apply this finding to product packaging and examine the effect of location on package evaluation. In Study 2, we show that there is no universal preference for heavy or light locations. For products for which heaviness is considered a positive attribute, packages with the product image placed at heavy locations are preferred, whereas for products for which heaviness is considered a negative attribute, packages using light locations are preferred. In Studies 3–4, we focus on the snack category, for which heaviness is good, and test moderating conditions for the preference for packages using heavy locations. In Study 3, we identify consumer goal as a moderator, such that a salient health goal, as opposed to a neutral goal, weakens the preference for packages using heavy locations. We also provide evidence that this moder-

Table 1
PRODUCT IMAGE LOCATION OBSERVED IN THE SNACK CATEGORY

A: Summary Statistics

Snack Type	*Cookie*	*Cracker*
Number of packages[a]	138	141
Product image on the package facade	100%	100%
A single image (cluster)	88%	84%
Package facade shape 1: vertical rectangle	41%	67%
Package facade shape 2: horizontal rectangle	47%	26%
Package facade shape 3: square	12%	8%
Health claim on the package facade	28%	61%
Product image placed at the light locations	30%	41%

B: Product Image Location as a Function of Snack Type and Health Claim

	Cookie (n = 138)		*Cracker (n = 141)*	
	Health Claim: No (n = 100)	*Health Claim: Yes (n = 38)*	*Health Claim: No (n = 55)*	*Health Claim: Yes (n = 86)*
Product image location placed at light locations	17 (17%)	25 (66%)	26 (47%)	33 (38%)

[a]If a package facade contained a transparent window, we excluded that package from our analysis to focus on product graphics only. We excluded 24 cookie and cracker packages.

ating effect of goal is weaker for healthful snacks than for regular snacks, echoing the results from our field study. In Study 4, we identify store shelf context as another moderator. Specifically, the location effects on perceived product heaviness and package evaluation appear in a contrasting context but disappear in an assimilating context. Moreover, we establish that perceived product heaviness mediates (1) the location effect on package evaluation and (2) the moderating role of store shelf context (i.e., mediated moderation).

STUDY 1: THE LOCATION EFFECT ON VISUAL HEAVINESS PERCEPTION

Perceptions about the lifted weight of physical objects as a function of seeing and feeling the objects have been extensively studied in experimental psychology. For example, a heavily researched effect is the size–weight illusion in which bigger objects of the same weight feel lighter (Charpentier 1891). Conversely, perceived visual weight of pictorial objects has been examined in the art and design literature from a Gestalt psychology perspective (e.g., Arnheim 1974). Here, it is shown that artists can skillfully distribute perceived visual weight by assigning pictorial objects to different locations of a visual field to achieve a perceptual balance in the artwork and to convey certain meanings to the viewer.

On the basis of the Gestalt whole–part relationship, Arnheim (1974) argues that no object is perceived as isolated; that is, seeing an object involves assigning it a place in the whole, for example, a location in space. A visual field's "structural skeleton" (i.e., the boundaries, center, and axes of symmetry) serves as a frame of reference for assigning location to an object within the field. This location further determines the object's visual weight. The relationship between location and visual weight can be described as "bottom-heavy" (i.e., as a pictorial object moves from the top to the bottom along the vertical axis of a visual field, it appears heavier) and "right-heavy" (i.e., as a pictorial object moves from the left to the right along the horizontal axis of a visual field, it also appears heavier). According to Arnheim, both bottom-heavy and right-heavy are "perceptual forces." That is, they are the counterpart of physical forces in visual perception. He argues that bottom-heaviness occurs because of gravitational pull and right-heaviness occurs because of the lever effect.

In a world dominated by gravitational pull, heavy things are anchored on the ground, while things of little weight (e.g., balloons) float upward. Therefore, people's visual weight judgments are in line with these bottom-heavy or top-light observations. This visual perception is so powerful that designers tend to make the bottom part of a visual object appear heavier. As Greenough (1947, p. 24) observes, "That buildings, in rising from the earth, be broad and simple at their bases, that they grow lighter not only in fact but in expression as they ascend, is a principle established. The laws of gravitation are the root of this axiom. The spire obeys it. The obelisk is its simplest expression." This visual tradition is even observed in situations in which the force of gravity is not directly relevant. Typographers design the lower part of a letter or number to be slightly bigger than the upper part. For example, 3, 8, S, and B look comfortably poised in their upright position but "macrocephalic" (the condition of having a head that is excessively large) when turned upside down (Kanizsa and Tampieri 1968).

One explanation for right-heaviness is based on one of the principles of the lever. This principle states that the greater the distance on the lever from the fulcrum position that an object is placed, the heavier is the weight that is needed on the other side to balance the object. On the basis of this mechanism, Arnheim (1974) proposes a two-step explanation for the right-heavy perception. First, pictures are "read" from left to right, and this is why the diagonal that runs from bottom-left to top-right is perceived as ascending and the other diagonal (i.e., top-right to bottom-left) as descending (i.e., if "read" from right to left, these two diagonals will then be perceived as descending and ascending, respectively [Wolfflin 1950]). Second, because the eyes enter a visual field from the left, the left naturally becomes the anchor point or "visual fulcrum." Thus, the further an object is placed away from the left side (or the fulcrum), the heavier is the perceived weight. Although this "visual level effect" was Arnheim's theory, he had no direct empirical evidence for it.

However, subsequent research in the field of ocular dominance (i.e., eye dominance or eyedness) has provided support for Arnheim's (1974) theory of right-heaviness, albeit not necessarily directly through his lever principle. Ocular dominance is "the visual phenomenon where a functional ocular unilaterality exists in binocular vision—some sort of physiological preferential activity of one eye over that of the other when both are used together" (Ogle 1950).[1] Porac and Coren (1976) report that approximately 65% of the population is right-eye dominant, 32% is left-eye dominant, and 3% is ambiocular. (Bourassa, McManus, and Bryden [1996] report similar statistics based on a meta-analysis covering research from 1925 to 1992.) Porac and Coren also describe the influence of ocular dominance on perceptual processing. For example, relative to the nondominant eye, the dominant eye has greater voluntary muscle movement strength (Schoen and Schofield 1935), is more likely to provide the primary information for the computation of visual direction (Walls 1951), and has a higher input intensity (Francis and Harwood 1959). These observations point to a "visual ego" (the center point for egocentric localization) that resides in the dominant eye (Porac and Coren 1976).

Visual input from the dominant eye is accentuated during binocular viewing, suggesting that objects on the same side as the dominant eye are often overestimated. First, Coren and Porac (1976) found that objects presented to the dominant eye are perceived as bigger than the same objects presented to the nondominant eye. Scott and Sumner (1949) found that objects placed in front of the dominant eye are perceived as being closer to the observer. Mefferd and Wieland (1969) had participants bisect a horizontal line, and they found that the locus of the midpoint shifted toward the side of the dominant eye. That is, for right-eyed people, the right segment of the line seemed to "count" more. Finally,

[1]Ocular dominance was first documented in the sixteenth century (see Porta 1593). It is a striking phenomenon that can be demonstrated easily: First, hold a pencil directly in front of you. Then, keeping both eyes open, align its tip with a point on a distant wall. Now cover one of your eyes and see if the pencil remains in good alignment with the target. Now cover the other eye and see if the alignment maintains. If the pencil shifts out of the alignment when you cover the left (right) eye, you are categorized as a left-eyed (right-eyed) person.

as a indirect test of Arnheim's (1974) right-heavy principle, Hirata (1968) had right-eyed participants assign a visual balance point anywhere along the straight line anchored by two identical objects or two objects of different sizes. During binocular viewing, there was a clear tendency to set the balance point to the right of the physically expected balance point, proving that for right-eyed people, objects in the right visual field had greater visual weight. However, Hirata's study did not include left-eyed participants, who might exhibit the same, reduced, or reversed right-heavy perceptual tendency.

In light of Arnheim's (1974) bottom-heavy and right-heavy visual weight principles and the subsequent support for right–left visual weight asymmetry among right-eyed people (who make up 65% of the population), we predict general bottom-heavy and right-heavy effects across people, though because of individual differences in eyedness, the latter effect might be weaker than the former one.

H_1: A pictorial object placed at the bottom, right, and bottom-right of a visual field will be perceived as heavier than the same object placed at the top, left, and top-left, respectively.

Method

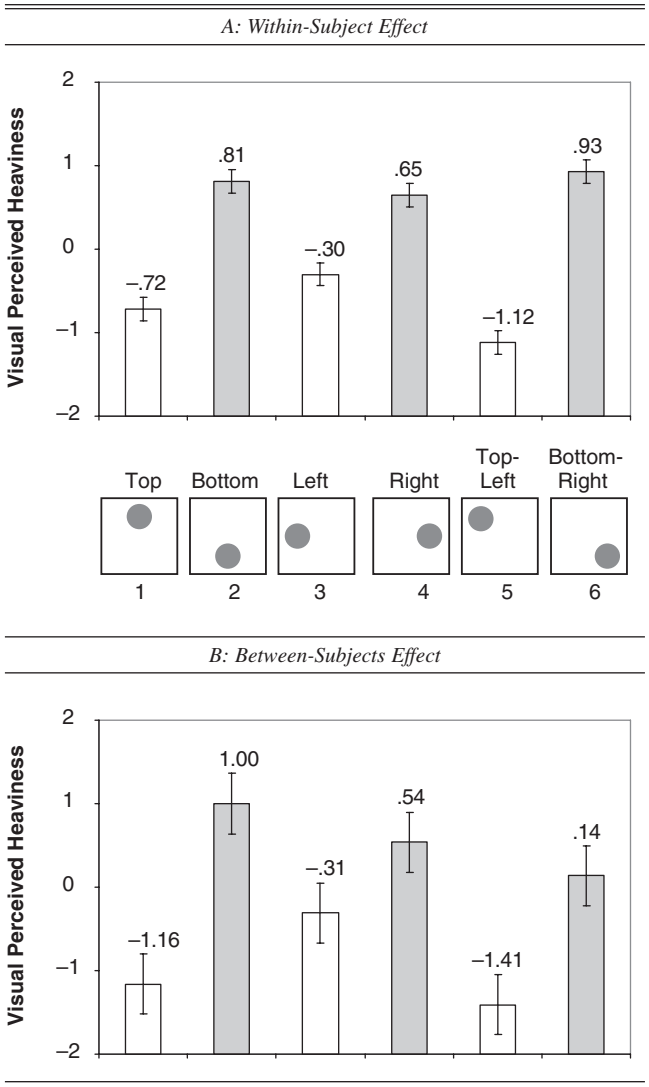
All experiments we report herein were computer based and conducted in the same behavioral laboratory. Participants were primarily students at a northeastern U.S. university who participated in experimental sessions containing several studies (of which our study was one) and were compensated $10 per hour. We conducted Study 1 (N = 139) to test H_1 using a one-factor (product image location: top, bottom, left, right, top-left, bottom-right; see the labels used in Figure 1) within-subject design. We prepared seven stimuli: one practice stimulus and six study stimuli. The six study stimuli were the labels used in Figure 1. In the practice stimulus, the disk was placed at the center of the square. We used a 6×6 Latin square to counterbalance the order of the six study stimuli, such that within a sequence, each stimulus appeared only once in each of the six positions, and across the six sequences, each stimulus followed each of the others only once. This design also enabled us to test H_1 as both a between-subjects study (using only the first stimulus each participant rated) and a within-subject study (using all stimuli). Participants rated the practice stimulus and then the six study stimuli, one at a time, on three nine-point scales (–4 = "unsubstantial/weightless/feathery," and 4 = "substantial/weighty/hefty").

Results

"Location" as a within-subject factor. We averaged the three scales to form a perceived heaviness index ($\alpha = .87$). A repeated measures analysis of variance (ANOVA) with location as a within-subject factor conducted on this index revealed a significant main effect of location ($F(5, 665) = 48.5$, $p < .0001$, see Figure 1, Panel A).[2] Planned contrasts indicated that the object located at the bottom was perceived as visually heavier than the object located at the top ($M_{top} = -.72$, $M_{bottom} = .81$; $t(133) = 6.9$, $p < .0001$), the object at the right heavier than the object at the left ($M_{left} = -.30$, $M_{right} = .65$; $t(133) = 6.5$, $p < .0001$), and the object at the bottom-right heavier than the object at the top-left ($M_{top\text{-}left} = -1.12$, $M_{bottom\text{-}right} = .93$; $t(133) = 10.1$, $p < .0001$).[3] Thus, H_1 was supported. We also calculated a difference score based on the first two contrasts (i.e., $difference_{bottom\ vs.\ top} - difference_{right\ vs.\ left}$) for each participant. We found that this difference was significantly greater than zero ($t(133) = 2.3$, $p < .05$), suggesting that the bottom-heavy result is a stronger phenomenon than the right-heavy result.

"Location" as a between-subjects factor. A one-way ANOVA with location as a between-subjects factor conducted on the rating on the first stimulus revealed that the main effect of location was also significant ($F(5, 133) = 7.0$, $p < .0001$, see Figure 1, Panel B). Again, planned contrasts indicated that the object located at the bottom was perceived as visually heavier than the object located at the top ($M_{top} = -1.16$, $M_{bottom} = 1.00$; $t(133) = 4.3$, $p < .0001$), the object at the right heavier than the object at the left ($M_{left} = -.31$, $M_{right} = .54$; $t(133) = 1.7$, $p < .05$), and the object at the

Figure 1
A PICTORIAL OBJECT'S LOCATION WITHIN A VISUAL FIELD DETERMINES ITS VISUAL WEIGHT



[2]For the sake of brevity, in this article, we do not report results that are not statistically significant.

[3]We use one-tailed tests for all planned contrasts.

bottom-right heavier than the object at the top-left ($M_{top\text{-}left} = -1.41$, $M_{bottom\text{-}right} = .14$; $t(133) = 3.0$, $p < .005$). The planned contrast between bottom-heavy and right-heavy also indicated that the former was a stronger effect than the latter ($t(133) = 1.9$, $p < .05$).

The underlying mechanism for the right-heavy effect. Hirata's (1968) study reveals a right-heavy effect among right-eyed people. In Study 1, including both right-eyed and left-eyed participants, we found a right-heavy effect, but it was weaker than the bottom-heavy effect. From the findings that ocular dominance influences visual processing such that objects on the same side as the dominant eye are often overestimated in size (Coren and Porac 1976) and length (Mefferd and Wieland 1969), it might be conjectured that the reason the right-heavy effect was smaller than the bottom-heavy effect is related to heterogeneity in eyedness among the participants. To test this conjecture, we conducted Study 1a (N = 117).

Participants were shown (1) an object in the left visual field (see the "3" label in Figure 1); (2) an object in the right visual field (see the "4" label); (3) side-by-side presentation of 1 and 2, with 1 on the left side; and (4) side-by-side presentation of 1 and 2, with 1 on the right side, one at a time. We used four between-subjects conditions to counterbalance the order. The paired presentation in 3 and 4 was consistent with the experimental paradigm used in the ocular dominance studies.[4] We then assessed participants' eyedness using an unconscious sighting test, the "alignment test" (Crovitz and Zener 1962; Hirata 1968), described in n. 1.[5] Participants were instructed to perform the alignment test eight times with alternating hands and to report each time which eye led to an alignment failure. Those who reported stronger alignment for the right eye four times or more were categorized as right-eyed people; otherwise, they were categorized as left-eyed people. The results showed that 77% and 23% of the participants were right-eyed and left-eyed, respectively.

A 2 × 2 repeated measures ANOVA with location as a within-subject factor and eyedness as a between-subjects factor conducted on the perceived heaviness index ($\alpha = .82$) revealed a significant main effect of location ($F(1, 115) = 23.6$, $p < .0001$), a significant main effect of eyedness ($F(1, 115) = 5.2$, $p < .05$), and a significant interaction between the two ($F(1, 115) = 7.8$, $p < .01$). Planned contrasts indicated that the object located at the right side was perceived as visually heavier than the object located at the left side for right-eyed participants ($M_{left} = -.58$, $M_{right} = .55$; $t(115) = 8.0$, $p < .0001$) but not for left-eyed participants ($M_{left} = .29$, $M_{right} = .59$; $t(115) = 1.2$, $p > .1$). In other words, left-eyed participants perceived the object in the left visual field as significantly heavier than right-eyed participants ($t(115) = 3.5$, $p < .001$), though they perceived the object in the right visual field as equally heavy. Therefore, our conjecture that eyedness moderates the right-heavy perception was confirmed.

[4]Our analyses found no effect of stimulus presentation format (single versus pair), stimulus (left-right) position within a pair, and stimulus order. Thus, in the subsequent analyses, we collapsed data over these factors.

[5]For different tests for eyedness and the advantages of unconscious tests, see Porac and Coren (1976).

Discussion

In Study 1, using a square visual field, we established that a pictorial object's location within a visual field determines its visual weight. In our subsequent studies, we aim to add more external validity to our experimental stimuli, so we use six different shaped package facades, including those we identified in the field study and a circle-shaped package facade that has been observed in gourmet shops (e.g., Danish cookie tins), that display real product images as our stimuli (illustrated in an abstract form in Figure 2).

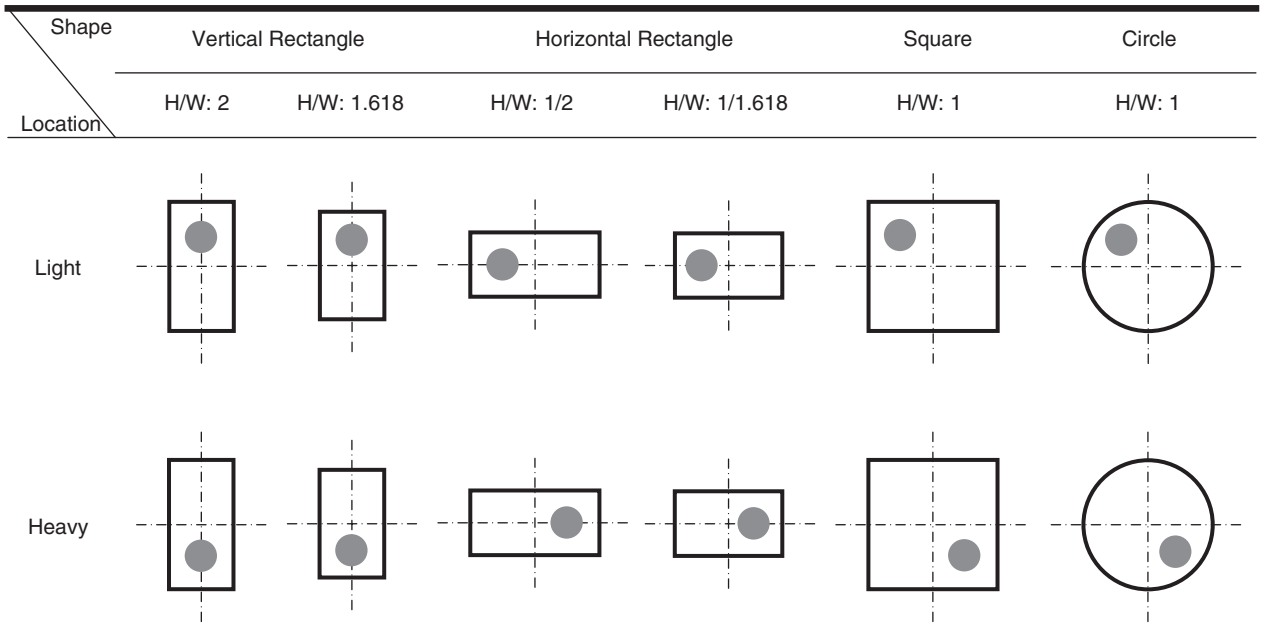
Although we gain generalizability using these more realistic package shapes, we also introduce a confound because the different shapes are conducive to different (heavy versus light) locations. For example, the bottom-heavy principle is not as relevant to the two horizontal rectangle shapes, because for these shapes there is not enough space for a pictorial object to vary significantly along the height dimension; similarly, the right-heavy principle is not as relevant to the two vertical rectangle shapes. Thus, we apply the bottom-heavy (right-heavy) principle only to the two vertical (horizontal) rectangle shapes. However, we can apply both principles to square and circle shapes. Therefore, we redefine heavy (light) as the bottom (top) of vertical rectangle shapes, the right (left) of horizontal rectangle shapes, and the bottom-right (top-left) of square and circle shapes. In our subsequent studies, the location effect on perceived product heaviness refers to the mean difference in perceived heaviness between products placed at heavy locations (Figure 2, bottom row) and products placed at light locations (top row). Similarly, the location effect on package evaluation refers to the mean difference in evaluation between packages using heavy locations (Figure 2, bottom row) and packages using light locations (top row). Finally, because in Study 1 we established the location effect in both a within-subject and a between-subjects experimental design, in the following studies, we manipulate location as a within-subject factor so that we have the power to test the location effect using a large number of different shapes.

Raghubir and Krishna (1999) demonstrate that consumers' volume perceptions determine their package preferences, such that the more voluminous the packages are perceived to be, the more they are preferred. Analogously, we argue that consumers' heaviness perceptions translate to their package preferences as well, such that the heavier the product appears to be from the package illustration, the more that package is preferred. On the basis of this argument, in Studies 2 and 3, we test the location effect on package evaluation directly without measuring perceived product heaviness to control for any potential carryover or demand effect that measuring the mediator might evoke. In Study 4, however, we explicitly test the hypothesized mediating role of perceived product heaviness.

STUDY 2: OVERALL VALENCE OF PRODUCT HEAVINESS MODERATES THE LOCATION EFFECT ON PACKAGE EVALUATION

As an attribute of a product, heaviness is not universally preferred. For some products, heaviness is considered positive (e.g., when weight is positively correlated with durability or richness in taste); however, for other products, heaviness is considered negative (e.g., when weight is negatively correlated with portability). Thus, higher levels of perceived

Figure 2
MANIPULATIONS OF PRODUCT IMAGE LOCATION AND PACKAGE FACADE SHAPE IN STUDIES 2–4



Notes: H/W: height/width ratio. H/W of 1.618 is the "golden" ratio, or golden section, that has been widely used in product design and package design (Bloch 1995; Raghubir and Greenleaf 2006). Studies 2 and 3 used all six shapes. Study 4 used the first four shapes.

heaviness may increase or decrease consumer utility as a function of the valence (positive or negative) assigned to that attribute. We note that the valence assigned to a product attribute may further be influenced by the consumer's current affect (Adaval 2001) or whether that attribute is aligned with a salient goal (Huffman and Houston 1993; Markman and Brendl 2000), which we address subsequently. If heaviness is considered positive (negative), product image locations that increase the perception of heaviness will be more (less) preferred. This is an important hypothesis because it suggests that there is no universally preferred product image location (e.g., the bottom or right side of the package facade), but preferred location is a function of the valence assigned to heaviness (as a product attribute) with respect to a specific product category.

Specifically, we investigate two groups of products in which the valence of heaviness differs. For snack products (e.g., ChocoStix wafer stick, Chips Ahoy chocolate chip cookie, and Oreo sandwich cookie), heaviness is good, because it suggests (1) "getting more" or (2) a richness in taste. In contrast, for nonfood items (e.g., Logitech QuickCam, Panasonic fluorescent bulb, and Ty Beanie Babies), heaviness is not good, because it suggests disadvantages regarding (1) safety (e.g., it is not safe when a heavy light bulb or computer-mounted video cameras falls out of place or when kids throw a heavy toy around or at each other) or (2) portability.

H_2: For products for which heaviness is considered positive, packages with the product image placed at heavy locations will be preferred. In contrast, for products for which heaviness is considered negative, packages with the product image placed at light locations will be preferred.

Method

We conducted Study 2 (N = 140) to test H_2 using a 2 (product image location: heavy versus light) × 2 (attribute valence: heaviness is positive versus heaviness is negative) within-subject design. Manipulation checks (conducted among a separate group of 124 participants) confirmed that heaviness was considered a positive attribute for the three snack products relative to the three nonfood products ($M_{difference}$ = 1.0 on a nine-point scale; t(122) = 5.2, $p < .0001$); whereas lightness was considered a positive attribute for the three nonfood products relative to the three snack products ($M_{difference}$ = 2.1; t(122) = 11.3, $p < .0001$).

For each of the six products, we prepared 12 schematic package facades similar to those shown in Figure 2, except that the axes were removed and the disk was replaced by the real product image. We organized the 72 stimuli into six groups of 12 stimuli, such that within each group, (1) heavy and light locations each occurred six times, (2) the six products each occurred twice, and (3) the six shapes each occurred twice. We used six sequences to counterbalance the stimulus order within each group. We randomly assigned participants to one of the 36 between-subjects conditions (i.e., 6 groups × 6 sequences).[6]

In the introduction to the study, participants were shown a sample schematic package facade along with the corresponding realistic package. This side-by-side comparison facilitated their understanding of how the schematic drawing translated to an actual package. Then, they viewed the 12 schematic packages assigned to them in pairs and evalu-

[6]Our analyses found no effect of the replicate Factors 2 and 3 and of stimulus order. We also found no effect of stimulus group and sequence. Thus, in the subsequent analyses, we collapsed data over these factors.

ated each package on three nine-point scales (–4 = "dislike/bad/unsatisfactory," and 4 = "like/good/satisfactory"). Presenting stimuli in pairs enabled us to reduce the number of Web pages participants needed to go through from 12 to 6, thus reducing participant fatigue. The results from Study 1a also indicated that stimulus presentation format (i.e., single versus pair) had no effect on visual weight.

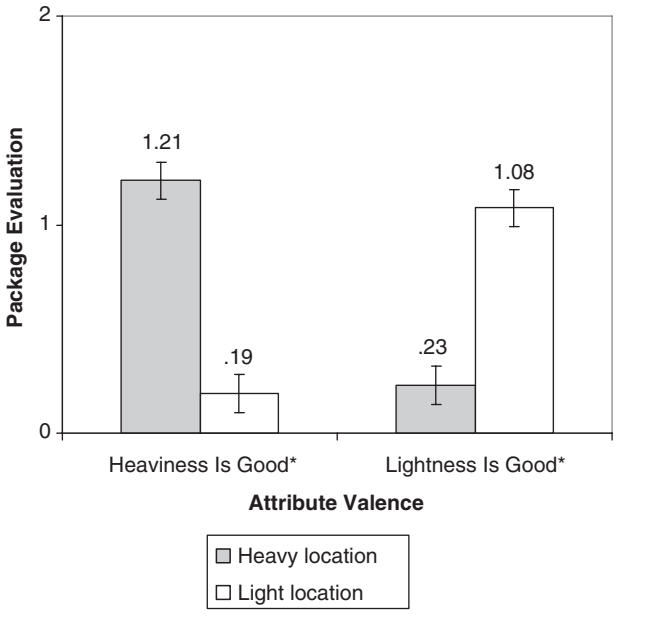
Results

We averaged the three scales to form a package evaluation index (α = .96). A 2 × 2 repeated measures ANOVA conducted on this index revealed a significant location × valence interaction ($F(1, 139) = 136.0$, $p < .0001$; see Figure 3). Planned contrasts showed that for products for which heaviness is good, packages with the product image placed at heavy locations were evaluated more favorably than packages with the product image placed at light locations ($M_{heavy} = 1.21$, $M_{light} = .19$; $t(139) = 9.0$, $p < .0001$). For products for which lightness is good, packages using heavy locations were evaluated less favorably than packages using light locations ($M_{heavy} = .23$, $M_{light} = 1.08$; $t(139) = –7.5$, $p < .0001$). Thus, H_2 was supported.

Discussion

In Study 2, we confirmed that there is no universally preferred product image location for package design and that preferred location is a function of the valence of heaviness in a specific product category. However, because we could not control for other attributes that might differ between the two groups of products, we cannot determine conclusively that the preferences for different product image locations were strictly a function of the different valences assigned to heaviness across the two groups. We remove this confound in Study 3 by keeping product category constant (i.e., focusing on the snack category for which heaviness is considered a positive attribute) and manipulate goal to induce differences in the valence assigned to heaviness. Study 3 will also help us understand the results of the field study by examining package evaluations for regular and healthful snacks and for snacks with and without a health claim.

Figure 3
PRODUCT ATTRIBUTE VALENCE MODERATES THE EFFECT OF PRODUCT IMAGE LOCATION ON PACKAGE EVALUATION



*$p < .0001$.

STUDY 3: CONSUMER GOAL MODERATES THE LOCATION EFFECT ON PACKAGE EVALUATION

Goals affect how consumers evaluate attribute levels (Huffman and Houston 1993; Markman and Brendl 2000) and assign valence (positive or negative) to a product attribute. In Study 2, we showed that when no goal was primed, consumers considered heaviness a positive attribute for regular snacks, which led to a preference for perceptual heaviness on the package. However, consumer goals, such as eating healthfully or being on a diet, could mitigate the positive valence of heaviness in the snack category. That is, a less positive valence might be assigned to heaviness because of its incompatibility with the consumer's health-related goal, and as a result, the preference for heavy product image locations on the package should become weaker. On the basis of this argument, we predict a two-way interaction between consumer goal and product image location, such that goal should moderate the preference for packages using heavy locations (see H_{3a}).

In addition to consumer goal, we can compare healthful snacks (e.g., crackers) with regular snacks (e.g., cookies). For consumers with a health goal, healthful snacks allow them to indulge themselves in snacking without compromising their heath goal. As a result, they should prefer "getting more" of healthful snacks and thus prefer perceptual heaviness on the package, resembling the tendencies consumers in the no-goal state exhibited for regular snacks in Study 2. Although a health goal will weaken the preference for packages using heavy locations (H_{3a}), this weakening effect should diminish for healthful snacks compared with regular snacks. In other words, we hypothesize a three-way interaction among snack type, consumer goal, and product image location, such that the two-way interaction described previously will be further moderated by snack type (see H_{3b}).

H_{3a}: There is a preference for packages with the product image placed at heavy locations under a neutral goal, but this effect will be weakened under a salient health goal.

H_{3b}: A salient health goal weakens the preference for packages with the product image placed at heavy locations for regular snacks, but this weakening effect will diminish for healthful snacks.

Method

We conducted Study 3 (N = 69) to test H_3 using a 2 (product image location: heavy versus light) × 2 (consumer goal: neutral versus health) × 2 (snack type: regular versus healthful) mixed design. Consumer goal was the only between-subjects factor, and we manipulated it using a scrambled sentence task (Srull and Wyer 1979). Regular snacks were represented by the three snack products used in Study 2. Healthful snacks were represented by reduced fat Nilla

Wafers, reduced fat Triscuit crackers, and reduced fat Wheat Thins.

As in Study 2, we prepared 72 package stimuli, 12 for each of the 6 snack products.[7] The stimulus construction and organization also followed Study 2. At the beginning of the study, participants were asked to complete 20 scrambled sentences, 10 of which contained a goal-priming word either for a health goal (e.g., low fat, salad, and workout) or for a neutral goal. Other aspects of this study were similar to Study 2, except that we used a single-scale measure of package evaluation (–4 = "dislike," and 4 = "like").

Results

A 2 × 2 × 2 repeated measures ANOVA conducted on package evaluation revealed a significant main effect of location ($F(1, 67) = 216.8$, $p < .0001$), a significant two-way interaction effect of location × goal ($F(1, 67) = 37.1$, $p < .0001$), and a marginally significant three-way interaction effect of location × goal × snack type ($F(1, 67) = 2.8$, $p < .1$). We report means and planned contrasts results in Table 2. Planned simple effect contrasts indicated a significant preference for heavy locations over light locations, which we refer to as "positive location effect" ($PLE = M_{heavy\ location} - M_{light\ location}$), in all conditions: 2.69 ($t(67) = 11.7$, $p < .0001$) under neutral goal and .87 ($t(67) = 3.6$, $p < .0005$) under health goal for regular snacks, and 2.19 ($t(67) = 9.5$, $p < .0001$) under neutral goal and 1.15 ($t(67) = 4.8$, $p < .0001$) under health goal for healthful snacks. However, consistent with H_{3a}, we found evidence that this preference for heavy locations was weakened by a health goal. Planned two-way interaction contrasts indicated a significantly positive "moderating effect of goal" ($MEG = PLE_{neutral\ goal} - PLE_{health\ goal}$) across both types of snacks: 1.82 ($t(67) = 5.5$, $p < .0001$) for regular snacks and 1.03 ($t(67) = 3.1$, $p < .005$) for healthful snacks. Finally, consistent with H_{3b}, we found evidence that this weakening effect of a health goal further diminished for healthful snacks. Planned three-way interaction contrasts indicated a significantly positive "moderating effect of (snack) type" ($MET = MEG_{regular\ snack} - MEG_{healthful\ snack}$): .78 ($t(67) = 1.7$, $p < .05$).

Discussion

In Study 3, we held product category constant and focused on the snack category, for which we demonstrated in Study 2 that heaviness was considered positive and thus perceptual heaviness was preferred over perceptual lightness on the package. We showed that compared with a neutral goal, a health goal weakened this preference (i.e., a goal × location two-way interaction). We also showed that this weakening effect of a health goal further diminished for healthful snacks compared with regular snacks (i.e., a snack type × goal × location three-way interaction).

The location effect manifested in the marketplace. In Study 3, we also provided some systematic evidence to support our field study findings. If we assume that a health claim on a package is promoting a health goal for consumers, the results in the field study parallel the results in Study 3. Specifically, the field study indicated that for regular snacks (i.e., cookies), packages with a health claim used light locations significantly more frequently than packages without a health claim (i.e., 66% versus 17%). This is consistent with the finding in Study 3 that a health goal significantly weakened the preference for heavy locations for regular snacks (i.e., $MEG_{Regular} = 1.82$). In addition, the field study indicated that for healthful snacks (i.e., crackers), packages with a health claim used light locations less frequently than packages without a health claim (i.e., 38% versus 47%). This is consistent with the finding in Study 3 that the weakening effect of health goal significantly diminished for healthful snacks (i.e., MET = .78). Overall, we observe considerable convergence between findings from the field study and lab Studies 1–3.

The location effect manifested in consumer designs. Studies 1–3 demonstrate that consumers respond in a predictive way to different product image locations constructed to test our theory. However, it would be worthwhile to test whether consumers actually have a mental model that is consistent with our theory. To explore this, we conducted Study 3a (N = 81).

Participants' task was to design two snack packages by placing several design elements in a package facade (design element and package facade were explained to them in simple terms). On the design Web page, four design elements

[7]As in Study 2, our analyses found no effect of the replicate factors, product instance and shape, and stimulus order. We also found no effect of stimulus group and sequence. Thus, in the subsequent analyses, we collapsed data over these factors.

(digital images of the snack, logo, snack name, and weight label) were scattered outside a rectangle. Participants were instructed to drag all four elements into the frame to form a package design. They could move elements around or click a "reset" button to try different compositions. When they were satisfied with the design, they could click a "finished" button to leave the page, at which point the location of each design element (x and y coordinates with the top-left corner of the frame as the point of origin) was recorded. After a practice design, all participants designed one cookie and one cracker package. Across the two snacks, the logo and the weight label were the same, but the snack image and product name were different. We used four between-subjects experimental conditions, such that participants in Conditions 1 and 2 designed on a horizontal rectangle package facade (height-to-width ratio = ½) and participants in Conditions 3 and 4 drew on a vertical rectangle frame (height-to-width ratio = 2). Orthogonal to the package facade shape, participants in Conditions 1 and 3 designed for the cookie first and then for the cracker, and in Conditions 2 and 4, this order was reversed.[8]

If consumers' lay theory agreed with our previous findings, we should observe that they use heavy locations more frequently than light locations for cookie images and do the opposite for cracker images. The results confirmed this predication. The relationship between snack image location and snack type was statistically significant ($\chi^2(2) = 10.8$, $p < .005$). Furthermore, 38% of the participants placed the cookie image at heavy locations, and 20% placed it at light locations of the package facade ($t(80) = 2.2$, $p < .05$); in contrast, 17% and 37% placed the cracker image at heavy and light locations, respectively ($t(80) = -2.5$, $p < .05$).

STUDY 4: PERCEIVED PRODUCT HEAVINESS MEDIATES THE LOCATION EFFECT ON PACKAGE EVALUATION AND THE MODERATING ROLE OF STORE SHELF CONTEXT

Although consumers may encounter a product package in isolation when they shop online, in bricks-and-mortar stores, a product package is almost always viewed in the context of other packages on a store shelf. Thus, in an actual retail store display, the perceived heaviness a consumer may experience from the graphics of a single package is likely to be moderated by the graphics of other nearby packages. If other packages on the shelf are similarly using product graphics, the effects of a single package are likely to be mitigated. Conversely, if other packages on the shelf are using product image locations in light positions, a single package with the product image in a heavy location is likely to have a more dramatic effect. Thus, the retailer's placement of other manufacturers' packages on the shelf can nullify or reinforce a single manufacturer's strategy for its own brand.

Research on attention allocation proposes that consumers attend to store shelf display through a two-process model. First, they allocate attentional resources evenly across the entire display with parallel processing of multiple stimuli. Second, they concentrate attentional resources on one display element, with serial processing of different stimuli (Jonides 1983). Behavioral decision research using eye-tracking data indicates that these two processes underlie a three-stage choice model of in-store purchase: The parallel processing underlies the first stage of choice called "orientation," in which shoppers overview the entire product display; the serial processing underlies the second and the third stages of choice called "evaluation" and "verification," respectively, in which shoppers compare between two or three alternatives and verify the tentatively chosen brand size (Russo and LeClerc 1994).

This literature suggests that store shelf context plays an important role in consumer perception and evaluation at the point of purchase. It also suggests that the effect of context on evaluation is mediated by perception. In this study, we test for this mediation mechanism.

The context effect literature distinguishes between two types of effects: contrast and assimilation. Contrast refers to the displacement of judgments away from the values of contextual stimuli, and assimilation refers to the displacement of judgments toward the contextual standard (Wedell 1994). Accordingly, we simulate two types of store shelf context. A contrasting context is formed when the target package is different from the contextual packages in terms of product image location (i.e., a heavy [light] target package is surrounded by light [heavy] packages). An assimilating context is formed when the target package is the same as the contextual packages in terms of product image location (i.e., a heavy [light] target package is surrounded by heavy [light] packages).

We propose that for packages with the product image placed at heavy (light) locations, a contrasting store shelf context will strengthen the perceptual heaviness (lightness) of the product, whereas an assimilating context will weaken this perception. That is, store shelf context is hypothesized to moderate the location effect on perceived product heaviness, such that contrasting contexts will accentuate and assimilating contexts will attenuate this effect. We illustrate this moderation mechanism in Figure 4 and outline it in H_{4a}.

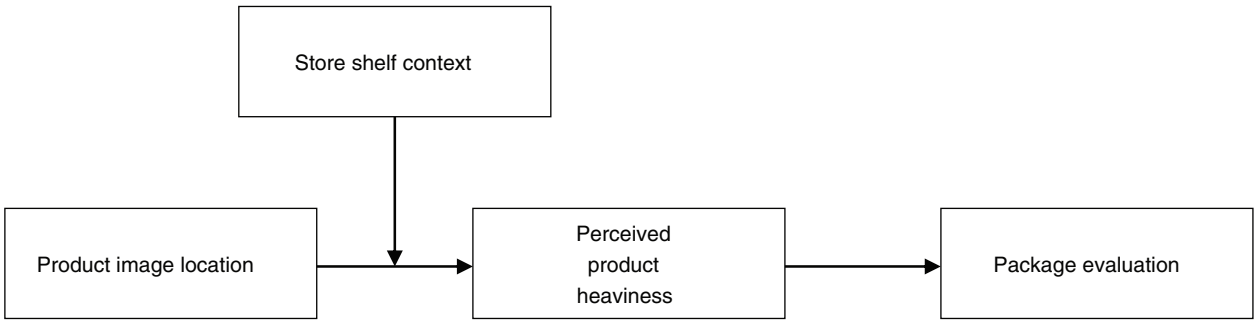
We then propose that consumers' perceptions of product heaviness will translate to their package evaluations. On the basis of this mediation hypothesis, we further propose that store shelf context will also moderate the location effect on package evaluation, such that contrasting contexts will accentuate and assimilating contexts will attenuate this effect. This is a "mediated moderation" because the hypothesized mediation process is responsible for this moderating effect (Muller, Judd, and Yzerbyt 2005).[9] In other words, if the perceived product heaviness does not mediate package evaluation, the moderating effect of store shelf context will stop at the perception stage without extending to the evaluation stage. We also illustrate this mediated moderation mechanism in Figure 4 and outline it in H_{4b}.

[8]Our analyses found no effect of package facade shape and snack order. Thus, in the subsequent analyses, we collapsed data over these factors.

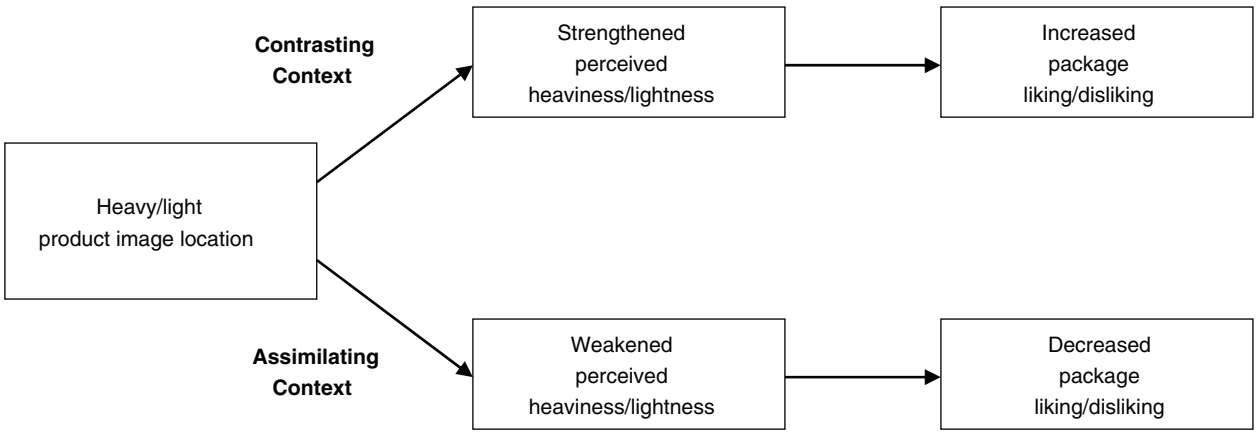
[9]Based on the mediation literature, in a mediated moderation, the path from the independent variable to the mediator (i.e., X → ME) depends on the level of the moderator, whereas the effect of the mediator on the dependent variable (i.e., ME → Y) is constant. In contrast, in a moderated mediation, the path from the independent variable to the mediator (i.e., X → ME) is constant, whereas the effect of the mediator on the dependent variable (i.e., ME → Y) depends on the level of the moderator. Here, we propose a mediated moderation rather than a moderated mediation because, in our case, the moderator is hypothesized to act on the X → ME path rather than the ME → Y path.

Figure 4
THE MODERATING ROLE OF STORE SHELF CONTEXT AND THE MEDIATING ROLE OF PERCEIVED PRODUCT HEAVINESS

A: The Mediated Moderation Model



B: Specific Effects of Contrasting and Assimilating Store Shelf Contexts



H_{4a}: Store shelf context moderates the location effect on perceived product heaviness.

H_{4b}: Perceived product heaviness mediates (i) the location effect on package evaluation and (ii) the moderating role of store shelf context in the location effect on package evaluation.

Method

We conducted Study 4 (N = 42) to test H_4 using a 2 (product image location: heavy versus light) × 2 (store shelf context: contrasting versus assimilating) within-subject design. We used the two regular snack products as in Studies 2 and 3—Chips Ahoy chocolate chip cookie and Oreo sandwich cookie—to construct the package stimuli.

To prepare the stimuli, for each of the two cookies, we designed 8 target packages using four different shapes. For each of the 8 target packages, we created a store shelf simulation by surrounding it with 31 contextual packages that were of the same four different shapes and various snack products. The target package was colored, while all contextual packages were black-and-white. In total, we created 16 store shelf simulations (see the Web Appendix at http://www.marketingpower.com/jmrdec09). They were organized into four groups of four stimuli, such that within each group, (1) target packages using heavy and light locations each occurred twice, (2) contrasting and assimilating contexts each occurred twice, (3) the two cookies each occurred twice, (4) the four shapes of target package each occurred once, and (5) the four locations of the target package on the shelf each occurred once. Moreover, we used four sequences to counterbalance the stimulus order within each group.[10] Participants were randomly assigned to 1 of the 16 between-subjects conditions (i.e., 4 stimulus groups × 4 sequences).

In the introduction to the study, participants were shown a sample store shelf simulation composed of schematic package designs and the corresponding store shelf snapshot composed of realistic packages (see the Web Appendix at http://www.marketingpower.com/jmrdec09). Then, they viewed the four stimuli assigned to them one by one and, for each stimulus, rated the cookie in the target package on the

[10]Our analyses found no effect of the replicate factors 3, 4, and 5 on both perceived heaviness and package evaluation. We also found no effect of stimulus group and sequence. Thus, in the subsequent analyses, we collapsed data over these factors. However, we found that the effect of stimulus order was significant on perceived heaviness ($p < .01$, the stimuli in the second and third positions were rated higher than the stimulus in the first position) but not on package preference. This is the only significant order effect we observed across all studies. Because we always controlled for order by counterbalancing, this result does not compromise our conclusions.

three scales used to measure perceived heaviness in Study 1. Finally, they viewed the four stimuli again, one at a time, and rated the target package on the three scales used to measure package evaluation in Study 2.

Results

Perceived product heaviness. We averaged the three scales used to measure perceived product heaviness to form a perceived heaviness index ($\alpha = .83$). A 2 × 2 repeated measures ANOVA conducted on this index revealed a significant main effect of location ($F(1, 41) = 10.6$, $p < .005$) and a significant interaction effect of location × context ($F(1, 41) = 8.7$, $p < .01$; see Figure 5, Panel A). Planned contrasts showed that in the contrasting context, cookies placed at heavy locations were perceived as visually heavier than cookies placed at light locations ($M_{heavy} = .43$, $M_{light} = -.72$; $t(41) = 4.4$, $p < .0001$); however, this effect disappeared in the assimilating context. Thus, H_{4a} was supported.

Package evaluation. The three scales used to measure package evaluation were averaged to form a package evaluation index ($\alpha = .96$). The same ANOVA conducted on this index revealed a significant main effect of location ($F(1, 41) = 7.5$, $p < .01$) and a significant interaction effect of location × context ($F(1, 41) = 7.9$, $p < .01$; see Figure 5, Panel B). Planned contrasts showed that in the contrasting context, packages with the product image placed at heavy locations were evaluated more favorably than packages with the product image placed at light locations ($M_{heavy} = .88$, $M_{light} = -.54$; $t(41) = 3.9$, $p < .0005$); however, this effect again disappeared in the assimilating context. Thus, we provide evidence that the moderation of store shelf context in the location effect on perceived heaviness carries over to package evaluation.

Mediation and mediated moderation analyses. To test H_{4b}, we estimated the six regression models that Muller, Judd, and Yzerbyt (2005, Equations 1–6) suggest. Models 1–3 tested the mediation hypothesis ($H_{4b(i)}$):

(1) $\text{Package evaluation} = \beta_{10} + \beta_{11}\text{location} + \varepsilon_1$,

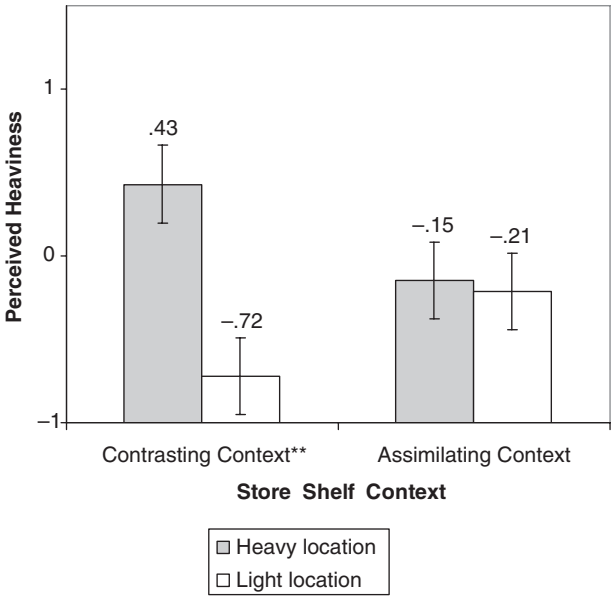
(2) $\text{Perceived heaviness} = \beta_{20} + \beta_{21}\text{location} + \varepsilon_2$, and

(3) $\text{Package evaluation} = \beta_{30} + \beta_{31}\text{location} + \beta_{32}\text{perceived heaviness} + \varepsilon_3$.

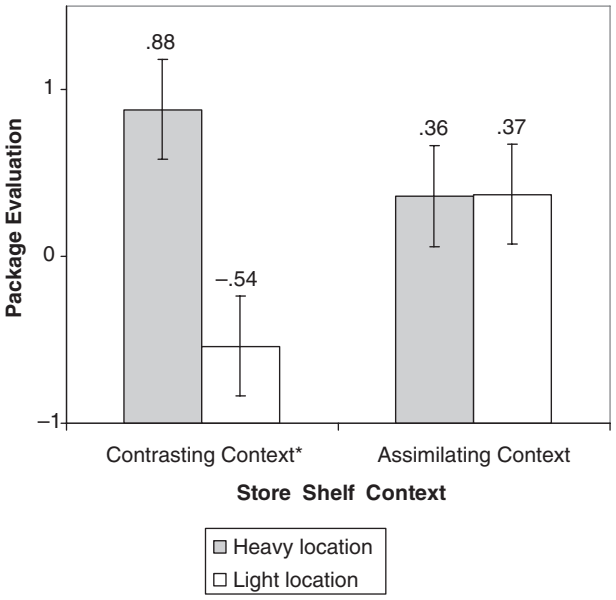
We report the results in Table 3. For Model 1, the overall effect of location on package evaluation, b_{11}, was significant; for Model 2, the effect of location on the mediator, b_{21}, was also significant; and for Model 3, the effect of the mediator on package evaluation, b_{32}, was significant, but the residual direct effect of location on package evaluation (controlling for the mediator), b_{31}, was not, indicating that perceived heaviness fully mediates the effect of location on package evaluation. The Sobel (1982) test confirms that the indirect effect of location on package evaluation through the mediator was significant ($z = 2.4$, $p < .05$). Moreover, there was an equality relationship among the estimated parameters of these models, such that the difference between the overall effect and the residual direct effect of location on package evaluation ($b_{11} - b_{31}$) was equal to its indirect effect through the mediator ($b_{21} \times b_{32}$), demonstrating excellent model fit.

Figure 5
STORE SHELF CONTEXT MODERATES THE EFFECS OF PRODUCT IMAGE LOCATION ON PERCEIVED PRODUCT HEAVINESS AND PACKAGE EVALUATION

A: Perceived Product Heaviness



B: Package Evaluation



*$p < .0005$.
**$p < .0001$.

Models 4–6 tested the mediated moderation hypothesis ($H_{4b(ii)}$):

(4) $\text{Package evaluation} = \beta_{40} + \beta_{41}\text{location} + \beta_{42}\text{context} + \beta_{43}\text{location} \times \text{context} + \varepsilon_4$,

Table 3
REGRESSION COEFFICENTS (STANDARD ERRORS) FOR THE MEDIATION AND MEDIATED MODERATION ANALYSES IN STUDY 4

Mediation Model		*Intercept*	*Product Image Location (X)*			*Perceived Heaviness (ME)*	
1	Package evaluation (Y)	.27 (.15)	.35* (.15)				
2	Perceived heaviness (ME)	–.16 (.12)	.30* (.12)				
3	Package evaluation(Y)	.38** (.13)	.15 (.13)			.67*** (.08)	
Mediated Moderation Model		***Intercept***	***Product Image Location (X)***	***Store Shelf Context (MO)***	***Location × Context (X × MO)***	***Perceived Heaviness (ME)***	***Heaviness × Context (ME × MO)***
4	Package evaluation (Y)	.27 (.15)	.35* (.15)	–.10 (.15)	.36* (.15)		
5	Perceived heaviness (ME)	–.16 (.12)	.30* (.12)	.02 (.12)	.27* (.12)		
6	Package evaluation (Y)	.37** (.13)	.15 (.14)	–.10 (.13)	.17 (.14)	.65*** (.09)	.02 (.09)

*$p < .05$.
**$p < .005$.
***$p < .0001$.

(5) Perceived heaviness = $\beta_{50} + \beta_{51}$location + β_{52}context + β_{53}location × context + ε_5, and

(6) Package evaluation = $\beta_{60} + \beta_{61}$location + β_{62}context + β_{63}location × context + β_{64}perceived heaviness + β_{65}perceived heaviness × context + ε_6.

To establish mediated moderation, we should first observe an overall moderation of the location effect (i.e., β_{43} should be nonzero). The question then is whether the mediating process partially or fully accounts for this moderation. If it does, the moderation of the residual direct effect of the location should be reduced or eliminated compared with the moderation of the overall location effect; that is, β_{63} should be smaller in magnitude than β_{43}, or close to zero in the case of full mediation. The results supported this mechanism (see Table 3). For Model 4, the overall effect of location on package evaluation ($X \rightarrow Y$) depended on the level of the moderator (i.e., b_{43} was significant); for Model 5, the effect of location on the mediator ($X \rightarrow ME$) also depended on the level of the moderator (i.e., b_{53} was significant); and for Model 6, the effect of the mediator on package evaluation ($ME \rightarrow Y$) was significant (i.e., b_{64} was significant) but constant (i.e., b_{65} was not significant), and the residual direct effect of location on package evaluation (controlling for the mediator) did not depend on the moderator (i.e., b_{63} was not significant). This pattern indicated that perceived heaviness fully mediated the moderating role of context in the location effect on package evaluation (Muller, Judd, and Yzerbyt 2005, p. 856). The Sobel test confirmed that the (moderated) indirect effect of location on package evaluation through the mediator was significant ($z = 2.1$, $p < .05$). Moreover, an equality relationship existed among the estimated parameters of these models, such that the difference between the overall (moderated) effect and the residual (moderated) direct effect of location on package evaluation ($b_{43} - b_{63}$) was equal to its (moderated) indirect effect through the mediator ($b_{64} \times b_{53} + b_{65} \times b_{51}$), demonstrating excellent fit.

Discussion

In Study 4, we provided evidence that store shelf context moderated the location effect on perceived product heaviness, such that this effect appeared in a contrasting context but disappeared in an assimilating context. In addition, store shelf context moderated the location effect on package evaluation, such that this effect appeared in a contrasting context but disappeared in an assimilating context. Finally, the latter moderation was due to perceived product heaviness fully mediating the location effect on package evaluation.

GENERAL DISCUSSION

Summary

In this research, we examine the effects of a package design element—namely, the location of the product image within a package facade—on consumers' perceived product heaviness and package evaluations. A field study and a series of laboratory studies provide convergent evidence that this design element can be used strategically to create favorable perceptions about the product and evaluations toward the package.

Specifically, in a field study conducted in a metropolitan supermarket in the snack category, we find that the location of the snack image on a package facade varies systematically as a function of snack type (e.g., cookie versus cracker) and feature (e.g., containing healthful ingredients or not), suggesting that the location of the product image is used to communicate product information. In the art and visual perception literature, location is among the factors that determine a pictorial object's visual weight (e.g., Arnheim 1974). Drawing from this literature and the research

on ocular dominance (e.g., Porac and Coren 1976), in Study 1, we experimentally establish that heavy (light) locations are the bottom (top), right (left), and bottom-right (top-left) of a visual field because pictorial objects placed at these locations are perceived as heavier (lighter). We then apply this "location effect" to package graphic design. In Study 2, we demonstrate that for products for which heaviness is considered a positive attribute, packages with the product image placed at heavy locations are preferred, whereas for products for which heaviness is considered negative, packages using light locations are preferred. This suggests that there is no universal preference for heavy or light locations but that the placement of the product image should depend on the valence assigned to heaviness. Focusing on a product category for which heaviness is considered positive (i.e., the snack category), in Study 3, we show that consumers' salient health goal weakens the preference for packages using heavy locations. However, the influence of goal becomes weaker if the snack category is considered healthful. This suggests that in the snack category, the preferred product image location should be a function of snack type (e.g., regular versus healthful snacks) and consumer goal (e.g., dieters versus nondieters). These results are consistent with the field study findings. In Study 4, we explore another moderating condition for the location effect on package evaluation as well as the underlying mechanism. We discover that store shelf context first moderates the location effect on perceived product heaviness, such that this effect appears in a contrasting context but disappears in an assimilating context. Then, because perceived product heaviness mediates the location effect on package evaluation, the moderating effect of store shelf context further translates to package evaluation (i.e., mediated moderation), such that packages using heavy locations are evaluated favorably in a contrasting context but not in a assimilating context. Our analyses confirm both the mediation and the mediated moderation processes.

Contributions to the Literatures and Further Research

Visual perception. Bottom-heavy and right-heavy are two principles of visual weight in the literature of art and visual perception (e.g., Arnheim 1974). However, bottom-heavy has never been experimentally tested before, and right-heavy was tested only among right-eyed people (Hirata 1968). We experimentally test these two principles and confirm that eyedness moderates the right-heavy perception. We also apply these perceptual effects to the context of packaging and identify moderating conditions. In doing so, we contribute to the art and visual perception literature.

Research on consumer perceptual processing of visual cues has shown that consumers frequently make perceptual judgments (e.g., how big, how long, how many) based on visual cues (e.g., Folkes and Matta 2004; Krider, Raghubir, and Krishna 2001; Krishna 2006; Raghubir and Krishna 1999), and these judgments are often biased (for a review, see Krishna 2007). We also contribute to this line of more applied research by examining another perceptual judgment—namely, how heavy a product is perceived to be—and similarly illustrating systematic biases in this visual perception.

Packaging. Researchers in this area have examined how package shape affects evaluation through perceived volume (e.g., Krishna 2006; Raghubir and Krishna 1999; Wansink and Van Ittersum 2003; Yang and Raghubir 2005). We contribute by examining how the location of the product image on a package facade affects evaluation through perceived product heaviness. Perceived heaviness is a particularly notable construct, and further research should explore its antecedents and consequences in greater depth. According to Arnheim (1974), factors such as color, shape, size, direction, depth, isolation, and intrinsic interest can also determine visual weight. Among these factors, color and shape are particularly relevant to package graphic design. We conducted a preliminary study to test whether different colors induce differential visual heaviness perceptions and found support for this idea. We pretested the visual weight of ten colors (the three primary colors, two secondary colors, and five tertiary colors) that are commonly used in graphic design. We found that when saturation was held constant, these ten hues differed considerably from one another in visual weight. Furthermore, for each hue, the high-saturated color chip was perceived as significantly heavier than the low-saturated color chip. These preliminary findings suggest that color has a strong potential to influence package evaluation through perceived heaviness, and thus this is a fruitful area for further research. Container shape has been found to affect volume perception, such that the greater the height-to-weight ratio of a container, the greater is the estimated volume (i.e., the elongation effect; e.g., Raghubir and Krishna 1999). Shape can also affect visual weight perception, and we leave this topic for further research as well.
